Abstract

Existing algorithms have only limited ability to answer structural questions about subgroups G of $\mathrm{GL}(d, F)$ where F is a finite field. We discuss new and promising algorithmic approaches, both theoretical and practical, which as a first step construct a chief series for G .

1 Introduction

Research in Computational Group Theory has concentrated on four primary areas: permutation groups, finitely-presented groups, soluble groups, and matrix groups. It is now possible to study in some detail the structure of permutation groups having degrees up to about ten million; Seress [90] provides a detailed account of the relevant algorithms. We can compute *useful* descriptions for quotients of finitely-presented groups; O'Brien & Vaughan-Lee [83] computed a power-conjugate presentation for the largest finite 2-generator group of exponent 7, showing that it has order 7^{20416} . Practical algorithms for the study of polycyclic groups are described in [56, Chapter 8].

We contrast the success in these areas with the paucity of algorithms to investigate the structure of matrix groups. Let $G = \langle X \rangle \leq \mathrm{GL}(d, F)$ where $F = \mathrm{GF}(q)$. Natural questions of interest to group-theorists include: What is the order of G ? What are its composition factors? What are its Sylow subgroups? How many conjugacy classes of elements does it have? Such questions about a subgroup of S_n , the symmetric group of degree n , are answered both theoretically and practically using highly effective polynomial-time algorithms. However, for linear groups these can be answered only in certain limited contexts. As one indicator, it is difficult (using standard functions) to answer such questions about $\mathrm{GL}(8, 3)$ using either of the major computational algebra systems, **GAP** [43] and **MAGMA** [15].

A major topic of research over the past 15 years, the so-called “matrix recognition” project, has sought to address these limitations, by developing effective well-understood algorithms for the study of such groups. A secondary goal is to realise the performance of these algorithms in practice, via publicly available implementations.

Two approaches dominate. The *black-box approach*, discussed in Section 4, aims to construct a characteristic series \mathcal{C} of subgroups for G which can be readily refined to provide a chief series; the associated algorithms are independent of the given representation. The *geometric approach*, discussed in Section 5, aims to exploit the natural linear action of G on its underlying vector space to construct a composition

series for G ; the associated algorithms exploit the linear representation of G . Both approaches rely on the solution of certain key tasks for simple groups which we discuss in Section 3; we survey their solutions in Sections 6–9. Central to ensuring correctness are presentations for groups of Lie type on certain *standard generators*; these are discussed in Section 10. As we demonstrate in Section 11, the geometric approach is practically realised via a *composition tree*. In practice, the composition series produced from the geometric approach is readily modified to produce \mathcal{C} . In Section 12 we consider briefly algorithms which exploit this series and its associated *Trivial Fitting* paradigm to answer structural questions about G . While it is not yet possible to make definitive statements about the outcome of this project, a realistic and achievable goal is to provide effective well-understood algorithms to answer many questions for linear groups of “small” degree, say up to degree 20 defined over moderate sized fields.

In this paper, we aim to supplement and update the related surveys [60], [66], and [84], and its length precludes comprehensiveness. Our focus is exclusively on matrix groups defined over finite fields. Recently, Detinko and Flannery have developed algorithms to answer many questions when the defining field is a function field of zero or positive characteristic; see [41] for an excellent survey.

2 Basic concepts

We commence with a review of basic concepts.

2.1 Complexity

If f and g are real-valued functions, defined on all sufficiently large integers, then $f(n) = O(g(n))$ means $|f(n)| < C|g(n)|$ for some positive constant C and all sufficiently large n .

One measure of performance is that an algorithm is *polynomial in the size of the input*. If $G = \langle X \rangle \leq \text{GL}(d, q)$, then the size of the input is $O(|X|d^2 \log q)$ since each of the d^2 entries in a matrix requires $\log q$ bits.

2.2 Black-box groups

The concept of a *black-box group* was introduced in [6]. In this model, group elements are represented by bit-strings of uniform length; the only group operations permissible are multiplication, inversion, and checking for equality with the identity element. Permutation groups, groups of words with a confluent rewriting system, and matrix groups defined over finite fields are covered by this model.

Seress [90, p. 17] defines a *black-box algorithm* as one which does not use specific features of the group representation, nor particulars of how group operations are performed; it can only use the operations listed above. However, a common assumption is that *oracles* are available to perform certain tasks – usually those not known to be solvable in polynomial time.

One such is a *discrete log oracle*: for a given non-zero $\mu \in \text{GF}(q)$ and a fixed primitive element ω of $\text{GF}(q)$, it return the unique integer k in the range $1 \leq k < q$

for which $\mu = \omega^k$. The most efficient algorithms for this task run in sub-exponential time (see [91, Chapter 4]).

If the elements of a black-box group G are represented by bit-strings of uniform length n , then n is the *encoding length* of G and $|G| \leq 2^n$. If G is described by a bounded list of generators, then the size of the input to a black-box algorithm is $O(n)$. If G also has Lie rank r and is defined over a field of size q , then $|G| > q^{r^2}$, so $r = O(\sqrt{n})$ and $\log q = O(n)$.

2.3 Algorithm types and random elements

Most algorithms for linear groups are *randomised*: they rely on random selections. A *Monte Carlo* algorithm is a randomised algorithm which may return an incorrect answer to a decision question, and the probability of this event is less than some specified value. A *Las Vegas* algorithm is one which never returns an incorrect answer, but may report failure with probability less than some specified value. If one of the answers given by a Monte Carlo algorithm is always correct, then it is *one-sided*. We refer the reader to [5] for a discussion of these concepts.

Monte Carlo algorithms to construct the normal closure of a subgroup and the derived group of a black-box group are described in [90, Chapter 2].

Many of our algorithms use random search in a group $G \leq \text{GL}(d, q)$ to find elements having prescribed property \mathcal{P} . Examples include having a characteristic polynomial with a factor of degree greater than $d/2$ or order divisible by a prescribed prime.

A common feature is that these algorithms depend on detailed analysis of the **proportion** of elements of finite simple groups satisfying Property \mathcal{P} . Assume we determine a lower bound, say $1/k$, for proportion of elements in G satisfying \mathcal{P} . To find element satisfying \mathcal{P} by random search with a probability of failure less than a given $\epsilon \in (0, 1)$, we choose a sample of uniformly distributed random elements in G of size at least $\lceil -\log_e(\epsilon) \rceil k$.

Following [90, p. 24], an algorithm constructs an ϵ -uniformly distributed random element x of a finite group G if $(1 - \epsilon)/|G| < \text{Prob}(x = g) < (1 + \epsilon)/|G|$ for all $g \in G$; if $\epsilon < 1/2$, then the algorithm constructs *nearly uniformly distributed* random elements of G . Babai [4] presents a black-box Monte Carlo algorithm to construct such elements in polynomial time. An alternative is the *product replacement algorithm* of Celler *et al.* [32]. That this also runs in polynomial time was established by Pak [85]. For a discussion of both algorithms, see [90, pp. 26–30].

2.4 Some basic operations

Consider multiplying two $d \times d$ matrices. Its complexity is $O(d^\omega)$ field operations, where $\omega = 3$ if we employ the traditional algorithm. Strassen's divide-and-conquer algorithm [93] reduces ω to $\log_2 7$ but at a cost: namely, the additional complexity of an implementation and larger memory demands. Coppersmith & Winograd's result [38] that ω can be smaller than 2.376 remains of limited practical significance.

We can compute large powers m of a matrix g in at most $2 \lfloor \log_2 m \rfloor$ multiplications by the standard doubling algorithm: $g^m = g^{m-1}g$ if m is odd and $g^m = g^{(m/2)2}$

if m is even.

Lemma 2.1

- (i) *Multiplication and division operations for polynomials of degree d defined over $\text{GF}(q)$ can be performed deterministically in $O(d \log d \log \log d)$ field operations. Using a Las Vegas algorithm, such a polynomial can be factored into its irreducible factors in $O(d^2 \log d \log \log d \log q)$ field operations.*
- (ii) *Using Las Vegas algorithms, both the characteristic and minimal polynomial of $g \in \text{GL}(d, q)$ can be computed in $O(d^3 \log d)$ field operations.*

For the cost of polynomial operations, see [94, §8.3, §9.1, Theorem 14.14]. Characteristic and minimal polynomials can be computed in the claimed time using the Las Vegas algorithms of [2, 63] and [44] respectively. Neunhöffer & Praeger [80] describe Monte Carlo and deterministic algorithms to construct the minimal polynomial; these have complexity $O(d^3)$ and $O(d^4)$ respectively and are implemented in GAP.

2.5 The pseudo-order of a matrix

To determine the order of $g \in \text{GL}(d, q)$ currently requires factorisation of numbers of the form $q^i - 1$, a problem generally believed not to be solvable in polynomial time. Since $\text{GL}(d, q)$ has elements of order $q^d - 1$ (namely, Singer cycles), we cannot simply compute powers of g until we obtain the identity!

Celler & Leedham-Green [33] present the following algorithm to compute the order of $g \in \text{GL}(d, q)$.

- Compute a “good” multiplicative upper bound B for $|g|$.
- Now factorise $B = \prod_{i=1}^m p_i^{\alpha_i}$ where the primes p_i are distinct.
- If $m = 1$, then calculate g^{p^j} for $j = 1, 2, \dots, \alpha_1 - 1$ until the identity is constructed.
- If $m > 1$ then express $B = uv$, where u, v are coprime and have approximately the same number of distinct prime factors. Now g^u has order k dividing v and g^k has order ℓ say dividing u , and the order of g is $k\ell$. Hence the algorithm proceeds by recursion on m .

They prove the following:

Theorem 2.2 *If we know a factorisation of B , then the cost of the algorithm is $O(d^4 \log q \log \log q^d)$ field operations.*

We can readily compute in polynomial time a “good” multiplicative upper bound for $|g|$. Let the factorisation over $\text{GF}(q)$ of the minimal polynomial $f(x)$ of g into powers of distinct irreducible monic polynomials be given by $f(x) = \prod_{i=1}^t f_i(x)^{n_i}$, where $\deg(f_i) = e_i$. Then $|g|$ divides $B := \text{lcm}(q^{e_1} - 1, \dots, q^{e_t} - 1) \times p^\beta$, where $\beta = \lceil \log_p \max n_i \rceil$ and $\text{GF}(q)$ has characteristic p .

The GAP and MAGMA implementations of the order algorithm are very efficient, and use databases of factorisations of numbers of the form $q^i - 1$, prepared as part of the Cunningham Project [19].

From B , we can learn in polynomial time the *exact* power of 2 (or of any specified prime) which divides $|g|$. By repeated division by 2, we write $B = 2^m b$ where b is odd. Now we compute $h = g^b$, and determine (by powering) its order which divides 2^m . In particular, we can deduce if g has *even order*.

For most applications, it suffices to know the *pseudo-order* of $g \in \text{GL}(d, q)$, a more refined version of B . Leedham-Green & O'Brien [67, Section 2] define this formally and show that it can be computed in $O(d^3 \log d + d^2 \log d \log \log d \log q)$ field operations.

2.6 Straight-line programs

One may intuitively think of a *straight-line program* for $g \in G = \langle X \rangle$ as an efficiently stored group word on X that evaluates to g . While the length of a word in a given generating set constructed in n multiplications and inversions can increase exponentially with n , the length of the corresponding straight-line program is *linear* in n . Babai & Szemerédi [6] prove that every element of a finite group G has a straight-line program (SLP) in every generating set of length $O(\log^2 |G|)$. Both MAGMA and GAP use straight-line programs.

3 The major tasks

Recall that a group G is *quasisimple* if G is perfect and $G/Z(G)$ is simple. We identify three major problems which must be solved for a (quasi)simple group $G = \langle X \rangle$.

- (i) The *naming problem*: determine the name of G .
- (ii) The *constructive recognition problem*: construct an isomorphism (possibly modulo scalars) between G and a “standard” copy of G .
- (iii) The *constructive membership problem*: if $g \in G$, then write g as an SLP in X .

An algorithm to solve Problem (i) may simply establish that G *contains* a named group as its unique non-abelian composition factor. Such information is useful: if we learn that G is a member of a particular family of finite simple groups, then we can apply algorithms to G which are designed for this family.

For each finite (quasi)simple group, we designate one explicit representation as its *standard copy* and designate a particular generating set as its *standard generators*. For example, the standard copy of A_n is on n points and its standard generators are $(1, 2, 3)$ and $(3, \dots, n)$ for odd n , or $(1, 2)(3, \dots, n)$ for even n .

To aid clarity of exposition, we focus on the classical groups, where the standard copy is the natural representation. Let $H = \langle Y \rangle \leq \text{GL}(d, q)$ denote the natural representation of a classical group. Given as input an arbitrary permutation or projective matrix representation $G = \langle X \rangle$, a constructive recognition algorithm sets up an isomorphism between G and the natural projective representation of H .

To enable these constructions, we define *standard generators* \mathcal{S} for $H = \langle Y \rangle$. Assume we can solve the following problems:

1. Construct \mathcal{S} as SLPs in Y .

2. Construct the image $\bar{\mathcal{S}}$ of these standard generators in G as SLPs in X .

We may now define the isomorphism $\phi : H/Z(H) \longrightarrow G$ by mapping \mathcal{S} to $\bar{\mathcal{S}}$. If we can solve the constructive membership problem in H , then the image in G of an arbitrary element of H can be constructed: if h has a known SLP in \mathcal{S} then $\phi(h)$ is the SLP evaluated in $\bar{\mathcal{S}}$. Similarly if we can solve the constructive membership problem in G , then we can define $\tau : G \longrightarrow H/Z(H)$. We say that these isomorphisms are *constructive*.

4 The black-box approach

The *black-box group approach*, initiated and pioneered by Babai & Beals (see [7] for an excellent account), focuses on the abstract structure of a finite group G . Recall, for example from [56, pp. 31–32], that G has a characteristic series of subgroups:

$$1 \leq O_\infty(G) \leq S^*(G) \leq P(G) \leq G$$

where

- $O_\infty(G)$ is largest soluble normal subgroup of G , the *soluble radical*;
- $S^*(G)/O_\infty(G)$ is the socle of $G/O_\infty(G)$ and so is $T_1 \times \dots \times T_k$ where T_i non-abelian simple;
- $\phi : G \longrightarrow \text{Sym}(k)$ is the representation of G induced by conjugation on $\{T_1, \dots, T_k\}$ and $P(G) = \ker \phi$;
- $P(G)/S^*(G) \leq \text{Out}(T_1) \times \dots \times \text{Out}(T_k)$ and so is soluble;
- $G/P(G) \leq \text{Sym}(k)$ where $k \leq \log |G| / \log 60$.

In summary, the black-box approach aims to construct this characteristic series \mathcal{C} for $G \leq \text{GL}(d, q)$ using black-box algorithms. In 2009, as a culmination of 25 years of work, Babai, Beals & Seress [9] proved that, subject to the existence of a Discrete Log and the ability to factorise integers of the form $q^i - 1$ for $1 \leq i \leq d$, there exist black-box polynomial time Las Vegas algorithms to construct \mathcal{C} for a large class of matrix groups. We refer the reader to [7] and [9] for details.

In Section 12 we consider how the black-box approach underpins various practical algorithms for matrix groups.

5 Geometry following Aschbacher

By contrast, the *geometric approach* investigates whether a linear group satisfies natural and inherent geometric properties in *its action on the underlying space*. A classification of the maximal subgroups of $\text{GL}(d, q)$ by Aschbacher [3] underpins this approach. Let Z denote the group of scalar matrices of G . Then G is *almost simple modulo scalars* if there is a non-abelian simple group T such that $T \leq G/Z \leq \text{Aut}(T)$, the automorphism group of T .

We paraphrase Aschbacher's theorem as follows.

Theorem 5.1 *Let V be the vector space of row vectors on which $\text{GL}(d, q)$ acts, and let Z be the subgroup of scalar matrices of G . If G is a maximal subgroup of $\text{GL}(d, q)$, then one of the following is true:*

- C1. G acts reducibly.
- C2. G acts imprimitively: G preserves a decomposition of V as a direct sum $V_1 \oplus V_2 \oplus \cdots \oplus V_r$ of $r > 1$ subspaces of dimension s , which are permuted transitively by G , and so $G \leq \text{GL}(s, q) \wr \text{Sym}(r)$.
- C3. G acts on V as a group of semilinear automorphisms of a (d/e) -dimensional space over the extension field $\text{GF}(q^e)$, for some $e > 1$ and so G embeds in $\text{GL}(d/e, q^e)$. (This includes the class of “absolutely reducible” linear groups, where G embeds in $\text{GL}(d/e, q^e)$.)
- C4. G preserves a decomposition of V as a tensor product $U \otimes W$ of spaces of dimensions $d_1, d_2 > 1$ over F . Then G is a subgroup of the central product of $\text{GL}(d_1, q)$ and $\text{GL}(d_2, q)$.
- C5. G is definable modulo scalars over a subfield: for some proper subfield $\text{GF}(q')$ of $\text{GF}(q)$, $G^g \leq \text{GL}(d, q').Z$, for some $g \in \text{GL}(d, q)$.
- C6. For some prime r , $d = r^n$ and $q \equiv 1 \pmod{r}$, and G is contained in the normaliser of an extraspecial group of order r^{2n+1} , or of a group of order 2^{2n+2} and symplectic-type.
- C7. G is tensor-induced: it preserves a decomposition of V as $V_1 \otimes V_2 \otimes \cdots \otimes V_m$, where each V_i has dimension $r > 1$ and the set of V_i is permuted by G , and so $G/Z \leq \text{PGL}(r, q) \wr \text{Sym}(m)$.
- C8. G normalises a classical group in its natural representation.
- C9. G is almost simple modulo scalars.

While Aschbacher’s theorem is about maximal subgroups of $\text{GL}(d, q)$, it is repeatedly applied to obtain a statement about all subgroups of $\text{GL}(d, q)$. We summarise the outcome: a linear group preserves some natural linear structure in its action on the underlying space and has a normal subgroup related to this structure, or it is almost simple modulo scalars.

In broad outline, it suggests that a first step in investigating a linear group is to determine (at least one of) its categories in the Aschbacher classification. If a category is recognised, then we can investigate the group structure more completely using algorithms designed for this category. Usually, we have reduced the size and nature of the problem. For example, if $G \leq \text{GL}(d, q)$ acts imprimitively, then we obtain a permutation representation of degree dividing d for G ; if G preserves a tensor product, we now consider two linear groups of smaller degree. If a proper normal subgroup N exists, we recognise N and G/N recursively, ultimately obtaining a composition series for G .

The *base cases* for the geometric approach are groups in C8 and C9: classical groups in their natural representation, and other groups which are almost simple modulo scalars. Liebeck [68] proved that the maximal non-classical subgroups of $\text{GL}(d, q)$ have order at most q^{3d} , small by comparison with $\text{GL}(d, q)$ which has order $O(q^{d^2})$. Further, the absolutely irreducible representations of degree at most 250 of all quasisimple finite groups are now explicitly known: see Hiss & Malle [52] and Lübeck [72].

Landazuri & Seitz [65] and Seitz & Zalesskii [89] provide lower bounds for degrees

of nonlinear irreducible projective representations of finite Chevalley groups. They show that faithful projective representations in cross characteristic have degree that is polynomial in the *size of the defining characteristic*. Hence our principal focus is on matrix representations in defining characteristic.

5.1 Deciding membership of an Aschbacher category

In [84] we reported in some detail on the algorithms developed to decide if $G = \langle X \rangle \leq \mathrm{GL}(d, F)$, where $F = \mathrm{GF}(q)$, acting on the underlying vector space V , lies in one of the first seven Aschbacher categories. Consequently we only update that report. In Section 6.1 we report on a Monte-Carlo algorithm which decides if G is in C8.

5.1.1 Reducible groups

The MEATAXE of Holt & Rees [54] is a Las Vegas algorithm with complexity $O(d^4 \log q)$. A key component is a search in the F -algebra spanned by X for a random element whose characteristic polynomial has an irreducible factor of multiplicity one. The analysis of [54], completed in [59], shows that the proportion of such elements is at least 0.08.

Definition 5.2 Let f a monic irreducible polynomial over F . A matrix A with entries from F is *f -cyclic* if f divides the minimal polynomial $m(t)$ of A , but f does not divide $c(t)/m(t)$, where $c(t)$ is characteristic polynomial.

Glasby & Praeger [46] develop and analyse a test for irreducibility using this larger class of matrices, which contains as a subset those considered in [54].

5.1.2 C3 and C5

Holt *et al.* [55] present the SMASH algorithm: effectively an algorithmic realisation of Clifford's theorem [34] about decompositions of V preserved by a non-scalar normal subgroup of G .

If G acts absolutely irreducible, we apply SMASH to a normal generating set for its derived group G' to decide if G acts semilinearly. The polynomial-time algorithm of [45] to decide membership in C5 requires that G' acts absolutely irreducibly. Implementations of both are available in MAGMA.

Carlson, Neunhöffer and Roney-Dougal [37] present a polynomial-time Las Vegas algorithm to find a non-trivial “reduction” of an irreducible group G that either lies in C3 or C5, or whose derived group does not act absolutely irreducibly. In particular, they deduce that G is in one of C2, C3, C4, or C5; or obtain a homomorphism from G to $\mathrm{GF}(q)^\times$. An implementation is available in GAP.

5.1.3 Normalisers of p -groups

If G is in C6, then it has a normal subgroup R of order either r^{2n+1} (extraspecial) or 2^{2n+2} (symplectic-type).

Brooksbank, Niemeyer & Seress [24] present an algorithm to produce a non-trivial homomorphism from G to either $\mathrm{GL}(2m, r)$ or $\mathrm{Sym}(r^m)$ where $1 \leq m \leq n$. They prove that this algorithm runs in polynomial time when G is either the full normaliser in $\mathrm{GL}(d, q)$ of R , or $d = r^2$. The special case where $d = r$ was solved by Niemeyer [81]. Implementations are available in GAP and MAGMA.

5.1.4 Towards polynomial time?

A major theoretical challenge is the following: decide membership in a *specific* Aschbacher category in polynomial time. This we can always do for C1 and C8, and sometimes for C3, C5 and C6.

Recently Neunhöffer [79] has further developed and analysed variations of the SMASH algorithm, and has also reformulated the Aschbacher categories to facilitate easier membership problems. This work and the “reduction” algorithms of [24] and [37] suggest that, subject to the availability of discrete log and integer factorisation oracles, it may be possible using matrix group algorithms to construct in polynomial time the composition factors of G .

6 Naming algorithms

Let b, e be positive integers with $b > 1$. Recall that a prime r dividing $b^e - 1$ is a *primitive prime divisor* of $b^e - 1$ if $r | (b^e - 1)$ but $r \nmid (b^i - 1)$ for $1 \leq i < e$. Zsigmondy [100] proved that $b^e - 1$ has a primitive prime divisor unless $(b, e) = (2, 6)$ or $e = 2$ and $b + 1$ is a power of 2. Recall that

$$|\mathrm{GL}(d, q)| = q^{\binom{d}{2}} \prod_{i=1}^d (q^i - 1).$$

Hence primitive prime divisors of $q^e - 1$ for various $e \leq d$ divide both the orders of $\mathrm{GL}(d, q)$ and of classical groups.

We say that $g \in \mathrm{GL}(d, q)$ is a *ppd*($d, q; e$)-element (or sometimes simply a *ppd*-element) if its order is divisible by some primitive prime divisor of $q^e - 1$.

6.1 Classical groups in natural representation

Much of the recent activity on algorithms for linear groups was stimulated by Neumann & Praeger [77], who presented a Monte Carlo algorithm to decide whether or not a subgroup of $\mathrm{GL}(d, q)$ contains $\mathrm{SL}(d, q)$.

Niemeyer & Praeger [82] answer the equivalent question for an arbitrary classical group. Underpinning this work is a classification of the subgroups of $\mathrm{GL}(d, q)$ containing ppd-elements for $e > d/2$ obtained by Guralnick *et al.* [48]. The resulting Monte Carlo algorithms have complexity $O(\log \log d(\xi + d^\omega (\log q)^2))$, where ξ is the cost of selecting a random element and d^ω is the cost of matrix multiplication. For an excellent account, see [87]. Their implementation is available in MAGMA.

6.2 Black-box groups of Lie type

Babai *et al.* [8] present a black-box algorithm to name a group G of Lie type in known defining characteristic p . The algorithm selects a sample \mathcal{L} of random elements in G , and determine the three largest integers $v_1 > v_2 > v_3$ such that a member of \mathcal{L} has order divisible by a primitive prime divisor of one of $p^{v_i} - 1$. Usually $\{v_1, v_2, v_3\}$ determines $|G|$ and so name G . The algorithm of Altseimer & Borovik [1] distinguishes between $\mathrm{P}\Omega(2m+1, q)$ and $\mathrm{PSp}(2m, q)$ for odd $q > 3$. The central result of [8] is the following.

Theorem 6.1 *Given a black-box group G isomorphic to a simple group of Lie type of known characteristic, the standard name of G can be computed using a polynomial-time Monte Carlo algorithm.*

An implementation developed by Malle and O'Brien is distributed with GAP and MAGMA. It includes naming procedures for the other quasisimple groups: if the non-abelian composition factor is alternating or sporadic, then we identify it by considering the orders of random elements.

6.3 Determining the defining characteristic

Theorem 6.1 assumes that the defining characteristic of the input group of Lie type is *known*.

Problem 6.2 Let $G \leq \mathrm{GL}(d, q)$ where G is a group of Lie type in **unknown** defining characteristic r . Can we determine r ?

Liebeck & O'Brien [70] present a Monte Carlo polynomial-time black-box algorithm which proceeds recursively through centralisers of involutions of G to find $\mathrm{SL}(2, F)$, where F is a field in characteristic r . It is now easy to read off the value of r .

Kantor & Seress [62] prove that the three largest element orders determine the characteristic of Lie-type simple groups of odd characteristic, and use this result to underpin an alternative algorithm.

The former is distributed in MAGMA, the latter in GAP.

7 Constructing an involution centraliser

Involution centralisers played a key role in the classification of finite simple groups. They were also used extensively in early computations with sporadic groups; see for example [71]. Borovik [14], Parker & Wilson [86] and Yalçınkaya [99] consider them in the general context of black-box groups.

The centraliser of an involution in a black-box group having an order oracle can be constructed using an algorithm of Bray [17], who proves the following.

Theorem 7.1 *If x is an involution in a group H , and w is an arbitrary element of H , then $[x, w]$ either has odd order $2k+1$, in which case $w[x, w]^k$ commutes with x , or has even order $2k$, in which case both $[x, w]^k$ and $[x, w^{-1}]^k$ commute with x . If*

w is uniformly distributed among the elements of the group for which $[x, w]$ has odd order, then $w[x, w]^k$ is uniformly distributed among the elements of the centraliser of x .

Thus if the odd order case occurs sufficiently often (with probability at least a positive rational function of the input size), then we can construct nearly uniformly distributed random elements of the involution centraliser in Monte Carlo polynomial time. Of course, in practice, we can also use the output of the even-order case to obtain a generating set for the centraliser.

Parker & Wilson [86] prove the following.

Theorem 7.2 *There is an absolute constant $c > 0$ such that if H is a finite simple classical group of Lie rank r defined over a field of odd characteristic, and x is an involution in H , then $[x, h]$ has odd order for at least a proportion c/r of the elements h in H .*

For exceptional groups, they show that the analogous result is true for at least a positive proportion of elements h in H .

For each class of involutions, they find a dihedral group of twice odd order generated by two involutions of this class, and show that a significant proportion of pairs of involutions in this class generate such a dihedral group.

The work of Liebeck & Shalev [69, Theorem] implies that a constant number of elements now generates the centraliser of an involution with arbitrarily high probability.

For each sporadic group we can calculate explicitly the proportion of $[x, h]$ which have odd order. Since, for every class of involutions, this proportion is at least 17%, we can readily construct involution centralisers.

Holmes *et al.* [53] record the cost of constructing an involution centraliser.

Theorem 7.3 *Let H be a simple group of Lie type defined over a field of odd characteristic, having a black-box encoding of length n and equipped with an order oracle. Let ξ denote the cost of selecting a random element. The centraliser in H of an involution can be computed in time $O(\sqrt{n}(\xi + \rho) \log(1/\varepsilon) + \mu n)$ with probability of success at least $1 - \varepsilon$, for positive ε .*

8 Constructive recognition

Assume that we wish to construct isomorphisms between the natural projective representation of a given quasisimple group $H = \langle Y \rangle$ and a projective representation $G = \langle X \rangle$ of H . Recall from Section 3 that we achieve this by constructing standard generators in H as SLPs in Y , and the corresponding standard generators of G as SLPs in X .

8.1 Black-box classical groups

Kantor & Seress [60] prove the following.

Theorem 8.1 *There is a Las Vegas algorithm which, when given as input a black-box perfect group $G \leq \mathrm{GL}(d, q)$ where $G/Z(G)$ is isomorphic to a classical simple group C of known characteristic, produces a constructive isomorphism $G/Z \mapsto C$.*

Recall that $g \in G$ is p -singular if its order is divisible by p . A group of Lie type having defining characteristic p has a small proportion of p -singular elements. More precisely, the results of Isaacs, Kantor & Spaltenstein [58] and Guralnick & Lübeck [49] imply the following.

Theorem 8.2 *If G is a group of Lie type defined over $\mathrm{GF}(q)$, then $\frac{2}{5q} < \rho(G) < \frac{5}{q}$, where $\rho(G)$ denotes the proportion of p -singular elements in G .*

A necessary first step of the algorithm of [60] is to find an element of order p : hence its running time has a factor of $q = p^e$ and so it is not polynomial in the size of the input.

Brooksbank & Kantor [21] identify that the obstruction to a polynomial-time algorithm for constructive recognition of the classical groups is $\mathrm{PSL}(2, q)$. Babai & Beals [7] formulate the problem explicitly as follows.

Problem 8.3 Find an element of order p in $\mathrm{PSL}(2, p^e)$ as a word in its defining generators in polynomial time.

Since $\rho(\mathrm{PSL}(2, q)) \leq 2/q$, a random search will involve $O(q)$ selections.

A consequence of the work of Landazuri & Seitz [65] is that the degree of a faithful projective representation of $\mathrm{PSL}(2, q)$ in cross characteristic is polynomial in q rather than in $\log q$. Hence the critical case is a matrix representation of $\mathrm{SL}(2, q)$ in defining characteristic.

Conder & Leedham-Green [35] and Conder, Leedham-Green & O'Brien [36] present an algorithm which, subject to the existence of a Discrete Log Oracle, constructively recognises $\mathrm{SL}(2, q)$ as a linear group in defining characteristic in time polynomial in the size of the input. The principal result is the following.

Theorem 8.4 *Let G be a subgroup of $\mathrm{GL}(d, F)$ for $d \geq 2$, where F is a finite field of the same characteristic as $\mathrm{GF}(q)$; assume that G is isomorphic modulo scalars to $\mathrm{PSL}(2, q)$. Then, subject to a fixed number of calls to a discrete log oracle for $\mathrm{GF}(q)$, there is a Las Vegas algorithm that constructs an epimorphism from G to $\mathrm{PSL}(2, q)$ at a cost of $O(d^5 \tau(d))$ field operations, where $\tau(d)$ denotes the number of divisors of d .*

Brooksbank [20, 23] and Brooksbank & Kantor [21, 25] have exploited this work to produce better constructive recognition algorithms for black-box classical groups. We summarise the outcome.

Theorem 8.5 *There is a Monte Carlo algorithm which, when given as input a black-box G such that $C = G/Z(G)$ is $\mathrm{PSL}(d, q)$, $\mathrm{PSp}(2m, q)$ or $\mathrm{PSU}(d, q)$ or $\mathrm{P}\Omega(d, q)$ and a constructive recognition oracle for $\mathrm{SL}(2, q)$, outputs a constructive isomorphism $G/Z(G) \mapsto C$. The running time of the resulting algorithms is a polynomial in the input length plus the time of polynomially many calls to the $\mathrm{SL}(2, q)$ oracle.*

A partial implementation of the algorithm of [60], developed by Brooksbank, Seress and others, is available in GAP and MAGMA. The algorithm of [36] is available in MAGMA.

8.2 Classical groups in their natural representation

Leedham-Green & O'Brien [67] have developed constructive recognition algorithms for the classical groups, given as linear groups in odd defining characteristic. A key component is the use of involution centralisers. The structure of the centralisers for such groups is well-known; see, for example, [47, Table 4.5.1].

Let ξ denote an upper bound to the number of field operations needed to construct an independent (nearly) uniformly distributed random element of a group, and let $\chi(q)$ denote an upper bound to the number of field operations equivalent to a call to a discrete logarithm oracle for $\text{GF}(q)$.

Leedham-Green & O'Brien [67] prove the following.

Theorem 8.6 *There is a Las Vegas algorithm that takes as input a subset X of bounded cardinality of $\text{GL}(d, q)$, where X generates a classical group G , and returns standard generators for G as SLPs of length $O(\log^3 d)$ in X . The algorithm has complexity $O(d(\xi + d^3 \log d + d^2 \log d \log \log d \log q + \chi(q)))$ field operations if G is neither of type \mathbf{SO}^- or $\mathbf{\Omega}^-$. Otherwise the complexity is $O(d(\xi + d^3 \log d + d^2 \log d \log \log d \log q + \chi(q)) + \chi(q^2))$ field operations.*

We illustrate the algorithm for $H = \text{SL}(d, q)$. Let V denote its natural module with basis $\{e_1, \dots, e_d\}$. Leedham-Green & O'Brien [67] define standard generators $\mathcal{S} = \{s, \delta, u, v\}$ for H : the matrices s, δ, u lie in a copy of $\text{SL}(2, q)$ and act on $\langle e_1, e_2 \rangle$ as

$$s = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \quad \delta = \begin{pmatrix} \omega & 0 \\ 0 & \omega^{-1} \end{pmatrix} \quad u = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix};$$

v maps $e_1 \mapsto e_d \mapsto -e_{d-1} \mapsto -e_{d-2} \mapsto -e_{d-3} \cdots \mapsto -e_1$.

The input to the algorithm is $G = \langle X \rangle = \text{SL}(d, q)$. Its task is construct \mathcal{S} as SLPs in X .

If t is an involution in G , with eigenspaces E_+ and E_- then $C_G(t)$ is $(\text{GL}(E_+) \times \text{GL}(E_-)) \cap \text{SL}(d, q)$.

Definition 8.7 A *strong involution* in $\text{SL}(d, q)$ has its -1 -eigenspace of dimension in range $(d/3, 2d/3]$.

The steps of the recursive algorithm are:

1. Find and construct a strong involution t having its -1 -eigenspace of dimension e .
2. Now construct $C_G(t)$. Construct the direct summands of its derived group to obtain $\text{SL}(e, q)$ and $\text{SL}(f, q)$ as *subgroups* of G where $f = d - e$.
3. Construct standard generators for $\text{SL}(e, q)$ and $\text{SL}(f, q)$.
4. Construct the centraliser C of the involution

$$\begin{pmatrix} I_{e-2} & 0 & 0 \\ 0 & -I_4 & 0 \\ 0 & 0 & I_{f-2} \end{pmatrix}.$$

5. Within C solve constructively for the matrix g

$$\begin{pmatrix} I_{e-2} & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & I_{f-2} \end{pmatrix}.$$

6. Now we use g to “glue” the e -cycle c_e and f -cycle c_f together to obtain the d -cycle $c_e g c_f$.

The first step of the algorithm is to search for an element of $\mathrm{SL}(d, q)$ of even order that has as a power a strong involution. Lübeck, Niemeyer & Praeger [74] prove the following.

Theorem 8.8 *For an absolute positive constant c , the proportion of $g \in \mathrm{SL}(d, q)$ such that a power of g is a strong involution is at least $c/\log d$.*

Observe that Step 3 is recursive, prompting invocations of the same procedure for $\mathrm{SL}(e, q)$ and $\mathrm{SL}(f, q)$. Since g is a strong involution, each group has degree less than $2d/3$; as shown in [67, Section 2], the cost of these recursive calls does not affect the degree of complexity of the overall algorithm.

Recursion to smaller cases requires additional results about involutions other than those which are strong. We summarise the relevant results of [67].

Theorem 8.9 *For some absolute constant c , the proportion of $g \in \mathrm{SL}(d, q)$ such that a power of g is a “suitable” involution is at least c/d .*

The base cases for the recursion are $\mathrm{SL}(d, q)$ where $d \leq 4$. For $\mathrm{SL}(2, q)$ we use the algorithm of [36] to construct standard generators as SLPs in the input generators; for $\mathrm{SL}(3, q)$ we use the algorithm of [73]; for $\mathrm{SL}(4, q)$ we use the *involution-centraliser algorithm* of [53]. An implementation is distributed with MAGMA.

Black-box versions of these algorithms are being developed by Damien Burns. We are developing similar algorithms for classical groups in characteristic 2. As Theorem 8.2 indicates, the principal challenge is to construct a strong involution.

Brooksbank [22] also developed constructive recognition algorithms for classical groups in their natural representation: their effective cost is $O(d^5 \log^2 q)$, subject to calls to an $\mathrm{SL}(2, q)$ oracle.

8.3 Small degree matrix representations of $\mathrm{SL}(d, q)$

Let $\mathrm{SL}(d, q) \leq H \leq \mathrm{GL}(d, q)$ with $q = p^f$ where V is the natural module of H and V^* is its dual module. Define the Frobenius map $\delta : \mathrm{GL}(d, q) \mapsto \mathrm{GL}(d, q)$ by $(a_{i,j})^\delta = (a_{i,j}^p)$ for $(a_{i,j}) \in \mathrm{GL}(d, q)$.

Let H act on an irreducible $\mathrm{GF}(q)G$ -module W of dimension at most d^2 . For a discussion of such irreducible representations, see [68]. In particular, W is quasiequivalent to an irreducible section of $V \otimes V^{\delta^e}$, or $V^* \otimes V^{\delta^e}$ where $0 \leq e < f$.

Consider $V^* \otimes V$ with basis $\{e_i \otimes e_j \mid 1 \leq i, j \leq d\}$ and let

$$w := \sum_{i=1}^d e_i \otimes e_i, \quad U := \left\{ \sum_{i,j} \alpha_{i,j} e_i \otimes e_j \mid \sum_{i=1}^d \alpha_{i,i} = 0 \right\}, \quad W_1 := U \cap \langle w \rangle.$$

The *adjoint module* of V is $W := U/W_1$. If $d \bmod p \equiv 0$ then W has dimension $d^2 - 2$, otherwise $d^2 - 1$. The remaining irreducible representations of dimension at most d^2 are $V \otimes V^{\delta^e}$ and $V^* \otimes V^{\delta^e}$ where $0 < e < f$.

Magaard, O'Brien and Seress [75] describe algorithms which, given as input W , construct a d -dimensional projective representation of H .

Theorem 8.10 *Let $d \geq 2$ and let $q = p^f$ be a prime power. Let $\mathrm{SL}(d, q) \leq H \leq \mathrm{GL}(d, q)$ where H has natural module V . Suppose that H is given as $G = \langle X \rangle$ acting irreducibly on a \mathbb{F}_q -vector space W of dimension $n \leq d^2$.*

Given as input G , the value of d , and error probability $\epsilon > 0$, there is a Las Vegas algorithm that, with probability at least $1 - \epsilon$, sets up a data structure to construct the projective action of G on V in time $O(\xi d^2 \log q \log(1/\epsilon) + \rho_q d^9 \log^2 d \log^2 q)$.

The algorithms are specific to each representation type and in all but one case run in polynomial time. A common feature is to search randomly in G for (a power of) a Singer cycle s , and identify a basis for W consisting of eigenvectors for the action of s on $W \otimes \mathbb{F}_{q^d}$. Implementations are available in MAGMA.

Ryba [88] presented a polynomial-time Las Vegas algorithm that, given as input an odd defining characteristic absolutely irreducible representation of a finite Chevalley group, constructs its action on the adjoint module. Since the adjoint module of $\mathrm{SL}(d, q)$ has dimension at most $d^2 - 1$, a combination of Ryba's algorithm and that of [75] can be used to construct the action on the natural module.

8.4 Alternating groups

Beals *et al.* [12] prove the following.

Theorem 8.11 *Black-box groups isomorphic to A_n or S_n with known value of n can be recognised constructively, in $O(\xi n + \mu |X| n \log n)$ time, where ξ is the time to construct a random element, μ is the time for a group operation, and X is the input generating set for the group.*

Beals *et al.* [13] present a more efficient algorithm for the deleted permutation module viewed as a linear group. Implementations are available in GAP and MAGMA.

An alternative black-box algorithm, developed by Bratus & Pak [16], was further refined and implemented in MAGMA by Derek Holt.

8.5 Exceptional groups

Algorithms to recognise constructively matrix representations of the Suzuki, large and small Ree groups were developed by B  rnhielm [10, 11]. Implementations are available in MAGMA.

In ongoing work, Kantor and Magaard are developing black-box algorithms for the exceptional groups.

8.6 Sporadic groups

Wilson [96] introduced the concept of *standard generators* for the sporadic groups. Bray and he provide black-box algorithms for their construction. For further details, see the ATLAS WEB site [97].

9 The constructive membership problem

Recall our definition of the *constructive membership problem* for a quasisimple group $G = \langle X \rangle$: if $g \in G$ then write g as an SLP in X .

Assume we have solved the constructive recognition problem for G : namely, we have constructed standard generators \bar{S} for G as SLPs in X . If we can express $g \in G$ as an SLP in \bar{S} , then we rewrite the SLP in \bar{S} for g to obtain one in X . Hence we focus on the task of writing $g \in G$ as an SLP in \bar{S} .

9.1 Classical groups

Costi [39] has developed algorithms to write an element of a classical group H in its natural representation as an SLP on the standard generators of H . These algorithms are natural (but quite technical) extensions of row- and column operations, and have complexity $O(d^3 \log q)$ field operations.

Now consider the case where G is a defining characteristic (projective) irreducible representation of $SX(d, q)$. Again Costi [39] has developed algorithms to solve the membership problem in this case: these have complexity $O(d^4 n^3 \log^3 q + d^2 n^4 \log q)$ where n is the degree of G . Implementations of both are available in MAGMA.

We summarise his algorithm when G is an irreducible representation of $H := \text{SL}(d, q)$. Its key components are two polynomial-time algorithms for unipotent groups.

1. SUBSPACE-STABILISER ALGORITHM

Input: unipotent subgroup $K \leq \text{GL}(d, q)$ acting on underlying vector space V and $U \leq V$.

Output: a canonical element \bar{U} of the orbit of U under K ; and $k \in K$ such that $U^k = \bar{U}$, and generators for the stabiliser of U in K .

2. An algorithm to decide constructively membership in a unipotent group.

Assume that $H = \text{SL}(d, q)$. Let $G \leq \text{GL}(n, F)$ be a projective irreducible representation of H in defining characteristic acting on the underlying vector space V . Let $\phi : H/Z(H) \mapsto G$ be the corresponding isomorphism.

1. Let K be the maximal parabolic subgroup of $H = \text{SL}(d, q)$ that fixes the space spanned by the first element of the standard basis for the underlying

space of H . Namely, elements of H have shape

$$\begin{pmatrix} \det^{-1} & 0 & & 0 \\ \star & & & \\ \vdots & & \text{GL}(d-1, q) & \\ \star & & & \end{pmatrix}$$

where \star is an arbitrary element of $\text{GF}(q)$.

Since $K\phi$ is a p -local subgroup where p is the defining characteristic, it stabilises a proper $K\phi$ -submodule U of V .

2. Consider the elementary abelian subgroup E of H generated by elements

$$\begin{pmatrix} 1 & \star & \dots & \star \\ 0 & & & \\ \vdots & & I_{d-1} & \\ 0 & & & \end{pmatrix}$$

Use the Subspace-Stabiliser algorithm to construct $x \in E\phi$ as an SLP that maps $W := U^g$ to U .

Hence $U^{gx} = U$ and so the preimage of gx is in K . So we have “killed” the first row of the preimage of gx .

3. Dualise to kill first column, obtaining $g_1 := \begin{pmatrix} \alpha & 0 \\ 0 & A \end{pmatrix}$.
4. Observe that $t\phi := g_1^{-1} \cdot T_{1,j}^\phi \cdot g_1 \in E\phi$ where $T_{1,j}$ is transvection with non-zero entry in $(1, j)$ position. Use the constructive unipotent membership test for $t\phi$ in $E\phi$ to obtain its preimage $t \in E$.
5. Read off from t (a scalar multiple of) the j -th row of the preimage in $\text{SL}(d, q)$ of g_1 .
6. We have now reduced the constructive membership problem to the **natural representation** in rank $d - 1$; use the corresponding natural representation algorithm to solve this smaller problem.

The two “unipotent” components of this algorithm depend critically on the assumption that G is a matrix representation of H in defining characteristic.

In ongoing work, Murray, Praeger and Schneider are developing black-box algorithms to solve the problem for classical groups on our standard generators.

The black-box algorithms of [60, 21, 23] solve the same task on different and significantly larger set of standard generators. An implementation of [60] is available in MAGMA for $\text{SL}(d, q)$, as are implementations by Brooksbank of some small rank cases from [21, 23].

9.2 Other algorithms

The *centraliser-of-involution* algorithm [53] reduces the problem of testing whether an arbitrary $g \in G$ is an element of a fixed $H \leq G$ to instances of the same problem for $C_H(t)$ for (at most) three involutions $t \in H$. The reduction occurs in polynomial time. The algorithm is constructive: if $g \in H$ then it returns a word for

g in the generators of H . Our implementation uses COMPOSITIONTREE, described in Section 11, to solve the problem for each centraliser.

The Schreier-Sims algorithm, and its variations, solves the same problem. First introduced by Sims [92], it constructs a *base* for G which determines a stabiliser chain in G . For an introduction to this algorithm, see [84]; for an analysis, see [90, p. 64].

9.3 Sporadic groups

For each sporadic group, O'Brien and Wilson developed black-box algorithms which construct chains of subgroups, and provides a “good” base for the Schreier-Sims algorithm.

With this assistance, the Schreier-Sims and the *centraliser-of-involution* algorithms can solve the constructive membership problem for all ATLAS representations [97] of most sporadic groups; the exceptions are the Baby Monster and the Monster where strategies developed by Wilson and others are employed [98]. Implementations are available in MAGMA.

10 Short presentations

Standard generators are used to define a surjection from a supplied group $G = \langle X \rangle$ to a simple group H . Is this surjection an isomorphism? If not, what is its kernel? If we have a presentation \mathcal{P} for H on standard generators, then we can evaluate relations of \mathcal{P} in standard generators of G and so obtain normal generators for the kernel of the map from G to H . This motivates our interest in *short* presentations for groups of Lie type on particular generating sets.

Babai & Szemerédi [6] define the *length* of a presentation to be the number of symbols required to write down the presentation. Each generator is a single symbol, and a relator is a string of symbols, where exponents are written in binary. The length of a presentation is the number of generators plus the sum of the lengths of the relators. They also formulated the *Short Presentation Conjecture*: there exists a constant c such that every finite simple group G has a presentation of length $O(\log^c |G|)$.

Perhaps the best known family of presentations for the finite symmetric groups are those of Moore [76]; see also [40, 6.22]. There, the symmetric group S_n of degree n is presented in terms of the transpositions $t_k = (k, k+1)$ for $1 \leq k < n$, which generate S_n and satisfy the defining relations $t_k^2 = 1$ for $1 \leq k < n$, and $(t_{k-1}t_k)^3 = 1$ for $1 < k < n$, and $(t_jt_k)^2 = 1$ for $1 \leq j < k-1 < n-1$. For $n > 1$ the number of these relations is $n(n-1)/2$, and since each relator has bounded length, the presentation length is $O(n^2)$.

If, for example, S_n acts on deleted permutation module, then the cost of evaluating these relations is $O(n^5)$: this is **more expensive** than constructive recognition of this representation (which can be performed using the algorithm of [13]).

Hence a goal of both theoretical and practical interest is to obtain “short” presentations for the finite simple groups on particular generating sets.

A key step is to obtain short presentations for A_n and S_n . Independently in 2006, Bray, Conder, Leedham-Green, and O'Brien [18] and Guralnick, Kantor, Kassabov & Lubotzky [50] proved the following.

Theorem 10.1 *A_n and S_n have presentations with a bounded number of generators and relations, and length $O(\log n)$.*

This is best possible since it requires $\log n$ bits to represent n ; the previous best result was a modification of the Moore presentation having length $O(n \log n)$.

Recently Guralnick *et al.* [51] prove that A_n has a presentation on 3 generators, 4 relations, and length $O(\log n)$. Bray *et al.* [18] prove that S_n has a presentation of length $O(n^2)$ on generators $(1, 2)$ and $(1, 2, \dots, n)$, and at most 123 relations.

Problem 10.2 Is there a shorter presentation for S_n defined on generators $(1, 2)$ and $(1, 2, \dots, n)$ with a uniformly bounded number of relators?

In a major extension, Guralnick *et al.* [50] prove the following.

Theorem 10.3 *Every non-abelian finite simple group of rank n over $\text{GF}(q)$, with possible exception of Ree groups ${}^2G_2(q)$, has a presentation with a bounded number of generators and relations and total length $O(\log n + \log q)$.*

Again this is best possible. It exploits the following results.

- Campbell, Robertson & Williams [26]: $\text{PSL}(2, p^n)$ has a presentation on (at most) 3 generators and a bounded number of relations.
- Hulpke & Seress [57]: $\text{PSU}(3, q)$ has a short presentation.

In ongoing work, Leedham-Green and O'Brien are constructing explicit short presentations on our standard generators for the classical groups.

11 The composition tree

In ongoing work, Bäärnhielm, Leedham-Green and O'Brien have developed the concept of a *composition tree*, an integrated framework to realise and exploit the geometric approach. An early design was presented in [66]; our latest is implemented in MAGMA. Neunhöffer & Seress [78] are developing a variation in GAP.

A composition series for a group G can be viewed as a labelled rooted binary tree. The nodes correspond to sections of G , the root node to G . A node corresponds to a section H of G ; if it is not a leaf, then it has a left child corresponding to a proper normal subgroup K of H and a right child I isomorphic to H/K .

The right child is an image under a homomorphism. Usually these arise naturally from the Aschbacher category of the group, but we exploit additional homomorphisms, including the determinant map and some applicable to unipotent and soluble groups. The left child of a node is the kernel of the chosen homomorphism.

The tree is constructed in *right depth-first order*. Namely, we process the node associated with H : if H is not a leaf, construct recursively the subtree rooted at its right child I , then the subtree rooted at its left child K .

A *leaf* of the composition tree is usually a composition factor of G : however, it need only be simple modulo scalars, and cyclic factors are not necessarily of prime order.

Assume $\phi : H \mapsto I$ where $K = \ker \phi$. It is easy to construct I , since it is the image of H under a homomorphism ϕ . Sometime it is easy to construct theoretically generating sets for $\ker \phi$, for example if H is in Aschbacher category C3. Otherwise, we first construct a normal generating set for K by evaluating the relators in a presentation for I and then take its normal closure using the algorithm of [90, Chapter 2] to obtain a generating set for K .

To obtain a presentation for a node, we need only presentations for its associated kernel and image; an algorithm for this task is described in [66]. Hence inductively we require presentations only for the leaves. If we know a presentation on standard generators for the leaf, then this is used; otherwise we use the algorithm of Cannon [27] to construct such a presentation.

We solve the constructive membership problem *directly* for a *leaf* using the techniques of Section 9. If we solve the membership problem for the children of a node, then we readily solve the problem for the node, and so recursively obtain a solution for the root node.

Assume that $G = \langle X \rangle \leq \text{GL}(d, q)$ is input to COMPOSITIONTREE. Some of the algorithms used in constructing a composition tree for G are Monte Carlo. To verify the resulting construction, we write down a presentation for the group defined by the tree and show that G satisfies its relations.

The output of COMPOSITIONTREE is:

- A composition series $1 = G_0 \triangleleft G_1 \triangleleft G_2 \cdots \triangleleft G_m = G$.
- A representation $S_k = \langle X_k \rangle$ of G_k/G_{k-1} .
- Effective maps $\tau_k : G_k \rightarrow S_k$, $\phi_k : S_k \rightarrow G_k$. The map τ_k is an epimorphism with kernel G_{k-1} ; if $g \in S_k$, then $\phi_k(g)$ is an element of G_k satisfying $\tau_k \phi_k(g) = g$.
- A map to write $g \in G$ as an SLP in X .

12 Applications

Over the past decade, Cannon, Holt and their collaborators have pioneered the development of certain practical algorithms to answer structural questions about finite groups. These exploit knowledge of the characteristic series \mathcal{C} of a finite group G

$$1 \leq O_\infty(G) \leq S^*(G) \leq P(G) \leq G$$

and a refined series for the soluble radical $O_\infty(G)$:

$$1 = N_0 \triangleleft N_1 \triangleleft \cdots \triangleleft N_r = O_\infty(G) \triangleleft G$$

where $N_i \trianglelefteq G$ and N_i/N_{i-1} is elementary abelian. Since $G/O_\infty(G)$ has a trivial Fitting subgroup, we call it a *TF-group*.

The resulting framework is sometimes called the *Trivial Fitting model of computation*. It suggests the following paradigm to solve a problem.

Solve the problem first in G/N_r , and then, successively, solve it in G/N_i , for $i = r - 1, \dots, 0$.

Since $H := G/O_\infty(G)$ is a TF-group, with heavily prescribed structure, the problem may have a nice solution in H . In particular, we can usually readily reduce the problem for H to questions about almost simple groups. Increasingly explicit solutions are available for such groups.

Algorithms which use this paradigm include:

- Determine conjugacy classes of elements of G (see [28]).
- Determine conjugacy classes of subgroups of G (see [29]).
- Determine the automorphism group of G (see [30]).
- Determine maximal subgroups of G (see [31] and [42]).

While these algorithms are effectively black-box, their current implementations use the Schreier-Sims algorithm for associated computations and so are limited in range. Recently, Holt refined the output of COMPOSITIONTREE for a group G to obtain a chief series reflecting \mathcal{C} . In ongoing work Holt, Leedham-Green, O'Brien and Roney-Dougal are exploring how to exploit COMPOSITIONTREE and this chief series to provide basic infrastructure for these and related algorithms.

12.1 Exploiting data for classical groups

We briefly discuss two examples where available data for classical (and almost simple) groups can be exploited.

In 1963, Wall [95] described theoretically the conjugacy classes and centralisers of elements of classical groups. In ongoing work, Haller and Murray exploit this description and provide algorithms which construct these explicitly in the natural representation of groups contained in the conformal classical group (the group preserving the corresponding form up to scalars). The effective isomorphisms obtained from constructive recognition allow us to map the class representatives and centralisers from the natural copy to an arbitrary projective representation.

Kleidmann & Liebeck [64] describe some of the maximal subgroups of classical groups where the degree $d \geq 13$. In ongoing work, Bray, Holt and Roney-Dougal construct generating sets in the natural representation for geometric maximal subgroups, and all maximals for $d \leq 12$. Again the effective isomorphism returned by constructive recognition is used to construct their images in an arbitrary projective representation.

12.2 Constructing the automorphism group of a finite group

As one illustration of the paradigm, we sketch the algorithm of Cannon & Holt [30] to compute the automorphism group of a finite group G .

Recall that $H := G/O_\infty(G)$ permutes the direct factors of its socle S by conjugation. We embed H in the direct product D of $\text{Aut}(T_i) \wr \text{Sym}(d_i)$, where T_i occurs d_i times as socle factor of S . Now $\text{Aut}(H)$ is the normaliser of the image of H in D . Hence we effectively reduce the computation for the TF-group H to the finite simple case.

We now lift results through elementary abelian layers, computing $\text{Aut}(G/N_i)$ successively. Suppose $N \leq M \leq G$, where both M and N characteristic in G , and

M/N is elementary abelian of order p^d .

Assume $A_M = \text{Aut}(G/M)$ is known. All automorphisms of G fix both M and N . Observe that $A_N = \text{Aut}(G/N)$ has normal subgroups $C \leq B$ where B induces identity on G/M , and C induces identity on both G/M and M/N . A key observation is that M/N is an $\mathbb{F}_p(G/M)$ -module.

- Elements of C correspond to derivations from G/M to M/N and are obtained by solving system of equations over $\text{GF}(p)$.
- Elements of B/C correspond to module automorphisms of the $\mathbb{F}_p(G/M)$ -module M/N . We can choose M and N to ensure that these tasks “easy”.
- The remaining – and hardest – task is to determine the subgroup S of A_M which lifts to G/N . Observe that $S \leq A'$, the subgroup of A_M whose elements preserve the isomorphism type of the $F(G/M)$ -module M/N , and A' can be computed readily. If G/N is a split extension of M/N by G/M , then all elements of A' lift. Otherwise, we must test each element of A' to decide whether it lifts to G/N .
